

Gap Anisotropy and de Haas-van Alphen Effect in Type-II Superconductors

Kouji Yasui and Takafumi Kita

Division of Physics, Hokkaido University, Sapporo 060-0810, Japan

(February 1, 2008)

We present a theoretical study on the de Haas-van Alphen (dHvA) oscillation in the vortex state of type-II superconductors, with a special focus on the connection between the gap anisotropy and the oscillation damping. Numerical calculations for three different gap structures clearly indicate that the average gap along the extremal orbit is relevant for the magnitude of the extra damping, thereby providing support for experimental efforts to probe gap anisotropy through the dHvA signal. We also derive an analytic formula for the extra damping which will be useful to estimate angle- and/or band-dependent gap amplitudes.

A considerable number of materials have been found in the 1990s to exhibit de Haas-van Alphen (dHvA) oscillation in the superconducting vortex state [1], the phenomenon discovered by Graebner and Robbings in 2H-NbSe₂ [2]. Many theories have been put forward during the same period to explain this fundamental phenomenon observed in the system without a well-defined Fermi surface [1]. However, there is yet no established theory comparable with the normal-state Lifshitz-Kosevich (LK) theory [3]. Moreover, what is lacking seems to be a clear physical picture of the mechanism of the extra oscillation damping in the vortex state. To improve the situation, we present here a numerical study combined with an analytical one.

Novel aspects in our study are summarized as follows:

(i) We perform *three-dimensional* numerical calculations for the dHvA oscillations in the vortex state using the Bogoliubov-de Gennes equations. To date, numerical studies have been carried out only for the two-dimensional *s*-wave model, such as that of Norman *et al.* (NMA) [4]. Our results show that dHvA oscillations in three dimensions are quantitatively different in the vortex state from those in two dimensions.

(ii) To clarify *the connection between the oscillation attenuation and the gap anisotropy*, we use three different gap structures: *s*-wave, *d*-wave with four point nodes in the extremal orbit, and *p*-wave with a line node in the extremal orbit; see Eq. (3) below. It is thereby shown that the attenuation is determined by the average gap along the extremal orbit in zero magnetic field (see Fig. 1), in disagreement with the theory of Miyake [5]. This result still indicates that one can probe the angle- and/or band-dependent gap amplitude in zero field with the dHvA effect in the vortex state. The origin of the discrepancy from Miyake's result is discussed in some detail.

(iii) We derive *a new analytic formula for the extra Dingle temperature* in the vortex state:

$$k_B T_\Delta = 0.5 \tilde{\Gamma} \langle |\Delta_{\mathbf{p}}|^2 \rangle_{\text{eo}} \frac{m_b c}{\pi e \hbar} \frac{1 - B/H_{c2}}{B}. \quad (1)$$

Here, $\tilde{\Gamma} = 0.125$ is a dimensionless quantity characterizing the Landau-level broadening due to the pair potential,

$\langle |\Delta_{\mathbf{p}}|^2 \rangle_{\text{eo}}$ denotes the average gap along the extremal orbit in zero field, m_b is the band mass, and B and H_{c2} are the average flux density and the upper critical field, respectively.

Equation (1) is derived below through the second-order perturbation with respect to the pair potential, i.e., an approach from H_{c2} , which is useful to estimate the gap amplitude along the extremal orbit. A difference from Maki's formula [6] lies in the prefactor where the Fermi velocity v_F is absent. Indeed, a dimensional analysis on the second-order perturbation tells us that the Landau-level broadening in the vortex state should be of order $|\tilde{\Delta}^{(0)}(B)|^2 / \hbar \omega_c$, where $\hbar \omega_c$ is the cyclotron energy and $\tilde{\Delta}^{(0)}(B) \propto \sqrt{\langle |\Delta_{\mathbf{p}}|^2 \rangle_{\text{eo}} (1 - B/H_{c2})}$ is essentially the average gap along the extremal orbit. This leads to Eq. (1) except for the numerical constant.

Terashima *et al.* [7] reported a dHvA experiment on YNi₂B₂C where an oscillation (labeled α) is seen to persist down to a field of order $0.2H_{c2}$. On the other hand, a specific-heat experiment at $H = 0$ shows a power-law behavior $\propto T^3$ at low temperatures [8], indicating the existence of the gap anisotropy in this material. This gap anisotropy may also play an important role for the dHvA signal far below H_{c2} . By using Eq. (1), the average gap of this band α will be estimated at the end of the paper.

Model: Our starting point is the Bogoliubov-de Gennes equation for the quasiparticle wavefunctions $\mathbf{u}_s$ and $\mathbf{v}_s^*$ labeled by a quantum number s with a positive eigenvalue E_s :

$$\int d\mathbf{r}_2 \begin{bmatrix} \underline{\mathcal{H}}(\mathbf{r}_1, \mathbf{r}_2) & \underline{\Delta}(\mathbf{r}_1, \mathbf{r}_2) \\ -\underline{\Delta}^*(\mathbf{r}_1, \mathbf{r}_2) & -\underline{\mathcal{H}}^*(\mathbf{r}_1, \mathbf{r}_2) \end{bmatrix} \begin{bmatrix} \mathbf{u}_s(\mathbf{r}_2) \\ -\mathbf{v}_s^*(\mathbf{r}_2) \end{bmatrix} = E_s \begin{bmatrix} \mathbf{u}_s(\mathbf{r}_1) \\ -\mathbf{v}_s^*(\mathbf{r}_1) \end{bmatrix}. \quad (2)$$

Here $\underline{\Delta}$ is the pair potential and $\underline{\mathcal{H}}$ denotes the normal-state Hamiltonian in the external field $\mathbf{H} \parallel \hat{\mathbf{z}}$; both are 2×2 matrices to describe the spin degrees of freedom. We adopt as $\underline{\mathcal{H}}$ the free-particle Hamiltonian. As for the pair potential, we wish to consider three cases to yield the following energy gaps at $H = 0$:

$$\underline{\Delta}_{\mathbf{p}} = \begin{cases} \Delta_0 W_p i\sigma_y \\ \Delta_0 W_p \sin^2 \theta_{\mathbf{p}} \cos 2\varphi_{\mathbf{p}} i\sigma_y \\ \Delta_0 W_p \cos \theta_{\mathbf{p}} i\sigma_z \sigma_y \end{cases}, \quad (3)$$

where $\mathbf{p}$ is the momentum, W_p denotes some cut-off function with $W_{p_F} = 1$ (p_F : Fermi momentum), $\theta_{\mathbf{p}}$ ($\varphi_{\mathbf{p}}$) is the polar (azimuthal) angle, and σ_j 's are the Pauli matrices. The first one is the isotropic s -wave state, whereas the latter two have four point nodes (d -wave) and a line node (p -wave), respectively, in the extremal orbit of the xy plane perpendicular to $\mathbf{H} \parallel \hat{\mathbf{z}}$. It then turns out that the orbital part of the corresponding pair potentials in finite fields can be expanded with respect to $\mathbf{r} \equiv \mathbf{r}_1 - \mathbf{r}_2$ and $\mathbf{R} \equiv \frac{1}{2}(\mathbf{r}_1 + \mathbf{r}_2)$ as [9]

$$\Delta(\mathbf{r}_1, \mathbf{r}_2) = \frac{\mathcal{N}_f}{\sqrt{2}} \sum_{N_c} \tilde{\Delta}^{(N_c)}(B) \psi_{N_c \mathbf{q}}^{(c)}(\mathbf{R}_{\perp}) \sum_{N_r m p_z} (-1)^{N_r} \times \psi_{N_r m}^{(r)}(\mathbf{r}_{\perp}) \frac{e^{ip_z z/\hbar}}{L_z} \times \begin{cases} W_p \\ \frac{1}{2} W_p \sin^2 \theta_{\mathbf{p}} \\ W_p \cos \theta_{\mathbf{p}} \end{cases}. \quad (4)$$

Here N_c and N_r denote the Landau levels in the average flux density B , $\mathbf{q}$ is an arbitrarily chosen center-of-mass magnetic Bloch vector, and m signifies the relative angular momentum along the z axis so that $m=0, 0$, and ± 2 for the three cases, respectively, in a system with $\mathcal{N}_f^2/2$ flux quanta and the length L_z along the z axis. The arguments $\mathbf{r}_{\perp}$ and $\mathbf{R}_{\perp}$ denote the xy components, and p and $\theta_{\mathbf{p}}$ are to be evaluated at $p = (p_z^2 + \hbar^2 N_r / l_B^2)^{1/2}$ and $\theta_{\mathbf{p}} = \tan^{-1} \frac{\hbar \sqrt{N_r} / l_B}{p_z}$ with $l_B \equiv (\hbar c / eB)^{1/2}$. See ref. [9] for the expressions of the basis functions $\psi_{N_c \mathbf{q}}^{(c)}$ and $\psi_{N_r m}^{(r)}$.

A significant advantage of Eq. (4) is that the coefficients $\{\tilde{\Delta}^{(N_c)}\}_{N_c=0}^{\infty}$ completely specify the pair potential, and the first few terms suffice to describe those of $B \gtrsim 0.1 H_{c2}$ [10,11]. The self-consistent mean-field theory [4,12,11] predicts an oscillatory reentrant behavior of H_{c2} and $\tilde{\Delta}^{(N_c)}$. On the contrary, such a singular behavior of H_{c2} has never been identified definitely in any materials displaying the dHvA oscillation in the vortex state. Leaving the puzzling discrepancy for a future study, we here adopt the quasiclassical $\tilde{\Delta}^{(N_c)}$ rather than the fully self-consistent one, with the square-root behavior

$$\tilde{\Delta}^{(0)} = a(1 - B/H_{c2})^{1/2} \quad (5)$$

of the mean-field second-order transition for the dominant $N_c=0$ level. Then the best choice for $\{\tilde{\Delta}^{(N_c)}\}_{N_c=0}^{\infty}$ would be to use the results from the Eilenberger equations. Since our main interest lies in studying the differences in the oscillation damping among various gap structures, however, we here adopt a model form of $\tilde{\Delta}^{(N_c)}$ determined by requiring that the maximum of $\frac{1}{V} \int d\mathbf{R} \left| \int d\mathbf{r} \Delta(\mathbf{r}_1, \mathbf{r}_2) e^{-i\mathbf{p} \cdot \mathbf{r} / \hbar} \right|^2$ be equal to $\Delta_0^2 (1 - B/H_{c2})$, where V is the volume of the system and Δ_0 denotes the maximum energy gap of the weak-coupling theory at

$T = H = 0$. This is possible within the lowest-Landau-level approximation of retaining only $\tilde{\Delta}^{(0)}$, which is excellent for $B \gtrsim 0.1 H_{c2}$ [10,11]. The resulting $\tilde{\Delta}^{(0)}$ also displays the square-root behavior, and our numerical calculation shows that $a^2 \approx 0.5 \Delta_0^2$ in all the three cases. We are planning to report on the best choice for a from the Eilenberger equations.

The use of the quasiclassical pair potential (5) has an advantage: Self-consistent calculations for the continuum model [4] necessarily result in a rather small number of Landau levels below the Fermi energy ε_F , i.e., $N_F \sim 10$ at H_{c2} , hence failing to meet the condition $N_F \gg 1$ appropriate for real materials. The present calculation with Eq. (5) is free from such a limitation. We have performed calculations including about 50 Landau levels below ε_F for the extremal orbit at H_{c2} .

Since the relevant materials have large Ginzburg-Landau parameter $\kappa \gg 1$, we also neglect the screening in the magnetic field. Indeed, the effect has been shown to be irrelevant for the oscillation damping [1]. We put $T=0$, adopt $W_p = e^{-(\xi_p/0.1\varepsilon_F)^4}$ with ξ_p the normal-state one-particle energy measured from ε_F , and choose the cyclotron energy at H_{c2} as $\hbar\omega_{c2} = k_B T_c$, in accordance with $\hbar\omega_{c2}/k_B T_c = 1 \sim 3$ for real materials.

Numerical Method: To solve it numerically for the above model, we transform Eq. (2) into the eigenvalue problem for the expansion coefficients of $\mathbf{u}_s$ and $\mathbf{v}_s$ in the quasiparticle basis functions $\{\psi_{N\mathbf{k}\alpha}\}$, where $\mathbf{k}$ is a quasiparticle magnetic Bloch vector and α ($= 1, 2$) signifies twofold degeneracy of the orbital states [9]. Then it can be solved separately for each $\mathbf{k}\alpha$ due to the translational symmetry of the vortex lattice. The overlap integral between $\psi_{N_c \mathbf{q}}^{(c)}(\mathbf{R}_{\perp}) \psi_{N_r m}^{(r)}(\mathbf{r}_{\perp})$ and $\psi_{N_1 \mathbf{k}_1 \alpha_1}(\mathbf{r}_{1\perp}) \psi_{N_2 \mathbf{k}_2 \alpha_2}(\mathbf{r}_{2\perp})$ vanishes unless $\mathbf{q} = \mathbf{k}_1 + \mathbf{k}_2$ and $\alpha_1 = \alpha_2$ so that the calculations are simplified greatly. The corresponding eigenstate is labeled explicitly by $s = (\nu \mathbf{k} \alpha p_z \sigma)$ with ν (σ) the band (spin) index.

Numerical results: Figure 1(a) presents the oscillation of the s -wave magnetization as compared with the normal-state one. We see clearly that the oscillation frequency is unchanged from that of the normal state. With $\hbar\omega_c = k_B T_c$ at H_{c2} , the oscillation is observed to persist down to a rather low field of $H_{c2}/B \lesssim 1.8$, i.e., $B \gtrsim 0.55 H_{c2}$, which is lower than $0.8 H_{c2}$ where $\hbar\omega_c$ becomes equal to the spatial average of the energy gap: $\Delta_0(1 - B/H_{c2})^{1/2}$. This is partly because the gap is smaller within the extremal orbit, as shown by Brandt *et al.* [13]. The points with error bars in Fig. 1(b) comprise the corresponding Dingle plot for the extra damping factor R_s obtained by numerical differentiation. This extra damping at high fields shows the behavior $\propto 1 - B/H_{c2}$ in the logarithmic scale, but an irregularity sets in around $0.55 H_{c2}$ where the oscillation disappears. We attribute this irregularity to the effect of the bound-state formation in the core region. The lines are the predictions from various theoretical formulas. The Maki formula [6] repro-

FIG. 1. Left figures: the oscillatory part M_{osc} of the magnetization in the vortex state (full lines) as compared with the normal-state one (dotted lines) for the three cases of Eq. (3). Right figures: the corresponding Dingle plots (points with error bars) compared with theoretical predictions.

duces the correct functional behavior $\propto 1-B/H_{c2}$ at high fields, but the prefactor is too large. The NMA formula [4], deduced from the two-dimensional self-consistent numerical results with $N_F \sim 10$ at H_{c2} , clearly shows a more rapid attenuation incompatible with our numerical data. The theory of Dukan and Tešanović [14], which would predict $R_s = 0$ in the clean limit of $T = 0$, is also inconsistent with the data. The solid line is due to Eq. (1) derived below; it reproduces both the functional dependence and the attenuation magnitude of the numerical data.

The above discrepancy between our numerical results and those of NMA may be attributed mainly to a difference in dimension. Indeed, the dHvA signal in three dimensions differs from that of two dimensions in that some finite region δp_z around the extremal orbit is relevant. Most of the Landau levels in the region do not satisfy the particle-hole symmetry with respect to ε_F , so that the effect of the pair potential is rather small to be handled with the second-order perturbation. This may be the reason why the oscillation is more persistent in our three-dimensional numerical results. This point is crucial in our derivation of the analytic formula below.

Figures 1(c) and 1(d) show the results for the second energy gap in Eq. (3) which vanishes at four points on the Fermi surface along the extremal orbit. The damping is seen to be strong and not much different from the s -wave case. Equation (1) gives a good fit to the numerical data for $H_{c2}/B \lesssim 1.8$, thereby indicating that the average gap along the extremal orbit is relevant for the extra damping. This result is in disagreement with Miyake's theory that point nodes in the extremal orbit should weaken the attenuation [5]. Indeed, Miyake obtained his analytic formula by applying a semiclassical quantization condition for the expression of the electron number N at $B = 0$. Neither of his starting point $N(B=0)$ nor the use of the quantization condition may be justified for describing the dHvA signals observed mainly near H_{c2} .

In the line-node case of Figs. 1(e) and 1(f), in contrast, we observe a much weaker damping in favor of Miyake's idea [5]. However, the non-zero extra damping can only be explained by considering the contribution of some finite width near the extremal orbit. Using Eq. (1) to obtain the best fit to the numerical data, i.e., the solid line of Fig. 1(f), we estimate that the region $|p_z| \lesssim p_F \sin \frac{\pi}{5}$ contributes to the extra attenuation. This is in rough agreement with the estimation from the Fresnel integral $\int_{-\infty}^{\infty} \exp[-i(\sqrt{2\pi N_F} p_z/p_F)^2] dp_z$ which appears in obtaining the LK formula: Cutting the infinite integral at $\sqrt{2\pi N_F} |p_z|/p_F \sim 10$ with $N_F \sim 50$ yields a similar value for the relevant range of p_z .

Analytic Formula: The Luttinger-Ward free-energy functional corresponding to Eq. (2) is given by [15]

$$\Omega = -\frac{k_B T}{2} \sum_n \text{Tr} \ln \begin{bmatrix} \mathcal{H} - i\varepsilon_n \underline{1} & \underline{\Delta} \\ -\underline{\Delta}^* & -\mathcal{H}^* - i\varepsilon_n \underline{1} \end{bmatrix} \times \begin{bmatrix} e^{i\varepsilon_n 0_+} \underline{1} & \underline{0} \\ \underline{0} & e^{-i\varepsilon_n 0_+} \underline{1} \end{bmatrix} + \dots, \quad (6)$$

where $\varepsilon_n/\hbar$ is the Matsubara frequency and 0_+ is an infinitesimal positive constant. The terms $\dots$ may be expressed solely with respect to the pair potential so that they can be neglected in the present model to consider the oscillatory part. This Ω may be transformed into [15]

$$\Omega = - \sum_s \left[k_B T \ln(1 + e^{-E_s/k_B T}) + E_s \int |\mathbf{v}_s(\mathbf{r})|^2 d\mathbf{r} \right]. \quad (7)$$

Since we are interested in the extra damping in the vortex state, we adopt as E_s and $\mathbf{v}_s$ the expressions from the second-order perturbation with respect to $\underline{\Delta}$. They are

$$E_{N\mathbf{k}\alpha p_z \sigma} = |\xi_{N p_z \sigma}| + \eta_{N\mathbf{k} p_z}^{(1)} \text{sign}(\xi_{N p_z \sigma}), \quad (8)$$

$$\int |\mathbf{v}_{N\mathbf{k}\alpha p_z \sigma}(\mathbf{r})|^2 d\mathbf{r} = \theta(-\xi_{N p_z \sigma}) + \eta_{N\mathbf{k} p_z}^{(2)} \text{sign}(\xi_{N p_z \sigma}), \quad (9)$$

where $\theta(\xi)$ is the step function and $\eta_{N\mathbf{k} p_z}^{(n)} \equiv \sum_{N'} |\iint \psi_{N\mathbf{k}\alpha}^*(\mathbf{r}_{1\perp}) \psi_{N'\mathbf{q}-\mathbf{k}\alpha}^*(\mathbf{r}_{2\perp}) \frac{e^{-ip_z(z_1-z_2)/\hbar}}{L_z} \Delta(\mathbf{r}_1, \mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2|^2 / (\xi_{N p_z \sigma} + \xi_{N' - p_z - \sigma})^n$. The first terms on the right-hand

side of these equations are just the normal-state expressions. The second terms, on the other hand, denote the finite quasiparticle dispersion in the magnetic Brillouin zone and the smearing of the Fermi surface, respectively, due to the scattering by the growing pair potential. It is useful to express $\eta_{N\mathbf{k}p_z}^{(n)}$ in terms of $\tilde{\Delta}^{(0)}(B)$ and the cyclotron energy $\hbar\omega_c$ of the extremal orbit as

$$\eta_{N\mathbf{k}p_z}^{(n)} = \frac{|\tilde{\Delta}^{(0)}(B)|^2}{(\hbar\omega_c)^n} \tilde{\eta}_{N\mathbf{k}p_z}^{(n)}. \quad (10)$$

The quantity $\tilde{\eta}_{N\mathbf{k}p_z}^{(n)}$ thus defined is dimensionless, and we realize that the main B dependence in Eq. (10) lies in the prefactor $|\tilde{\Delta}^{(0)}(B)|^2/(\hbar\omega_c)^n$. The explicit expression of $\tilde{\eta}_{N\mathbf{k}p_z}^{(n)}$ is given by

$$\tilde{\eta}_{N\mathbf{k}p_z}^{(n)} = \frac{\mathcal{N}_f^2}{4} \sum_{N'm'm'} \frac{|\langle N N' | 0 N + N' \rangle|^2 \langle N + N' + m | 2\mathbf{k} - \mathbf{q} \rangle}{[N + N' - 2(N_F + \delta)]^n} \times \langle 2\mathbf{k} - \mathbf{q} | N + N' + m' \rangle \times \begin{cases} 1 \\ \sin^4 \theta_{\mathbf{p}} \\ \cos^2 \theta_{\mathbf{p}} \end{cases}, \quad (11)$$

where the overlap integrals are given by eqs. (3.23) and (3.29) of ref. [9], $\delta = \delta(B, p_z)$ ($|\delta| < 1/2$) specifies the location of ε_F between the two closest Landau levels, and $m, m' = 0, 0$, and ± 2 for the three cases of Eq. (4), respectively. The corresponding normalized density of states:

$$D_{Np_z}^{(n)}(\tilde{\eta}) \equiv \frac{2}{\mathcal{N}_f^2} \sum_{\mathbf{k}\alpha} \delta(\tilde{\eta} - \tilde{\eta}_{N\mathbf{k}p_z}^{(n)}), \quad (12)$$

will play a central role in the following.

Substituting eqs. (8) and (9) into Eq. (7), we find that the terms containing $\eta_{N\mathbf{k}p_z}^{(2)}$ may be neglected due to the cancellation between the particle and hole contributions. The remaining term can be transformed with the standard procedure. We thereby obtain, for the first harmonic of Ω/V , the expression:

$$\frac{\Omega_1}{V} = -\frac{k_B T}{2\pi^2 l_B^2} \sum_{\sigma} \int_{-1/2}^{\infty} dN \cos(2\pi N) \int_{-\infty}^{\infty} dp_z \int_{-\infty}^{\infty} d\tilde{\eta} \times D_{Np_z}^{(1)}(\tilde{\eta}) \ln[1 + e^{-(\xi_{Np_z\sigma} + \tilde{\eta} |\tilde{\Delta}^{(0)}(B)|^2 / \hbar\omega_c) / k_B T}]. \quad (13)$$

The function $D_{Np_z}^{(1)}(\tilde{\eta})$ depends on (N, p_z) , but may be replaced by a representative one $\overline{D}_{\ell}^{(1)}(\tilde{\eta})$ to be placed outside the N and p_z integrals [16], where the recovered index ℓ specifies the s -, d -, or p -wave case of Eq. (11). It may also be acceptable to use a Lorentzian for it: $\overline{D}_{\ell}^{(1)}(\tilde{\eta}) = \tilde{\Gamma}_{\ell} / \pi(\tilde{\eta}^2 + \tilde{\Gamma}_{\ell}^2)$ [17]. We thereby obtain an expression for the magnetization which carries an extra damping factor:

$$R_s(B) \equiv \int_{-\infty}^{\infty} \overline{D}_{\ell}^{(1)}(\tilde{\eta}) \exp[-2\pi i \tilde{\eta} |\tilde{\Delta}^{(0)}(B)|^2 / (\hbar\omega_c)^2] d\tilde{\eta} = \exp[-2\pi \tilde{\Gamma}_{\ell} |\tilde{\Delta}^{(0)}(B)|^2 / (\hbar\omega_c)^2]. \quad (14)$$

Thus, the superconductivity gives rise to an extra Dingle temperature of $k_B T_{\Delta} \equiv \tilde{\Gamma}_{\ell} |\tilde{\Delta}^{(0)}(B)|^2 / \pi \hbar \omega_c$, or equivalently, the extra scattering rate of $\tau_s^{-1} \equiv 2\pi k_B T_{\Delta} / \hbar$.

Equation (14) may have an advantage that one can trace the origin of the extra dHvA damping definitely to the growing pair potential, which brings about a finite quasiparticle dispersion (11) in the magnetic Brillouin zone and the corresponding Landau-level broadening, Eq. (12). Moreover, Eq. (11) reveals that this broadening near H_{c2} is closely connected with the zero-field gap structure, Eq. (3).

There seems to be no analytic way to estimate $\tilde{\Gamma}_s$, so we determine it using the best fit to the numerical data of Fig. 1(b). Using Eq. (5) with $a^2 = 0.5\Delta_0^2$, the procedure yields $\tilde{\Gamma} \equiv \tilde{\Gamma}_s = 0.125$, as noted before. It is also clear for the anisotropic cases that the average gap around the extremal orbit is relevant for the extra attenuation, as may be realized from Eq. (11). We hence put $a^2 \tilde{\Gamma}_{\ell} = 0.5 \langle |\Delta_{\mathbf{p}}|^2 \rangle_{\text{eo}} \tilde{\Gamma}_s$. We thereby obtain Eq. (1), which gives a good fit to the d -wave numerical data without any adjustable parameters; see Fig. 1(d).

Concluding Remarks: We have shown explicitly that the dHvA effect in the vortex state can be a powerful tool to probe the average gap along the extremal orbit. Such an experiment has recently been performed on UPd₂Al₃ by Inada *et al.* [18], and Eq. (1) will be useful in similar experiments to estimate angle- and/or band-dependent gap amplitudes. Using the α oscillation of YNi₂B₂C observed by Terashima *et al.* [7], for example, we obtain $\langle |\Delta_{\mathbf{p}}|^2 \rangle_{\text{eo}} = 1.5 \text{ meV}$ for this α band, a value much smaller than 2.5 meV from the specific-heat measurement [8]. It should be noted, however, that the numerical factor 0.5 in Eq. (1) comes from our model described below Eq. (5). It has to be replaced by the result from the Eilenberger equations. We are planning to report on this together with detailed comparisons with experiments in the near future.

We acknowledge stimulating discussions with Y. Inada and Z. Tešanović. We are also grateful for the hospitality of the members of Institut für Theorie der Kondensierten Materie at Universität Karlsruhe and Physikalisches Institut at Universität Bayreuth, where a part of the work has been performed. T.K. acknowledges Yamada Science Foundation for financial support. Numerical calculations were performed on an Origin 2000 in “Hierarchical matter analyzing system” at the Division of Physics, Graduate School of Science, Hokkaido University.

- [16] The p_z integral in Eq. (13) passes through regions where $\delta \approx 0$ in Eq. (11), i.e., the second-order perturbation is not justified. However, the main contribution to the integral certainly comes from the regions where we can use Eq. (8). Notice that $\delta = -1/8$ at the maximal orbit when the magnetization takes a local maximum.
- [17] It is found numerically that the variance of Eq. (12) depends little on the values of N_F and N ($\sim N_F$), as expected. It is ~ 0.2 for the s -wave pairing with $\delta = -1/8$.
